## Abstract

Human understanding of language is robust to different word choices as far as they represent similar semantic concepts. To what extent does our human intuition transfer to language models, which represent all subwords as distinct embeddings? In this work, we take an initial step on measuring the role of shared semantics among subwords in the encoder-only multilingual language models (mLMs). To this end, we form “semantic tokens” by merging the semantically similar subwords and their embeddings, and evaluate the updated mLMs on 5 heterogeneous multilingual downstream tasks. Results show that the general shared semantics could get the models a long way in making the predictions on mLMs with different tokenizers and model sizes. Inspections on the grouped subwords show that they exhibit a wide range of semantic similarities, including synonyms and translations across many languages and scripts. Lastly, we found the zero-shot results with semantic tokens are on par or even better than the original models on certain classification tasks, suggesting that the shared subword-level semantics may serve as the anchors for cross-lingual transferring.

## 1 Introduction

In current language models, all subwords are represented equally and individually in the word embeddings, yet is that truly necessary? Empirically, human’s perception on the sentence is robust regarding interchanging words under the same or similar semantic concept (Figure 1). The most obvious examples are the semantically equivalent words in different languages: code-switching “they” to “они”, or “tomatoes” to “tomate”.<sup>1</sup> The sentence meaning is preserved for people who understand both languages. The robustness may also apply to some of the inflectional changes: swapping “tomatoes” into “tomato”, while losing the plural form,

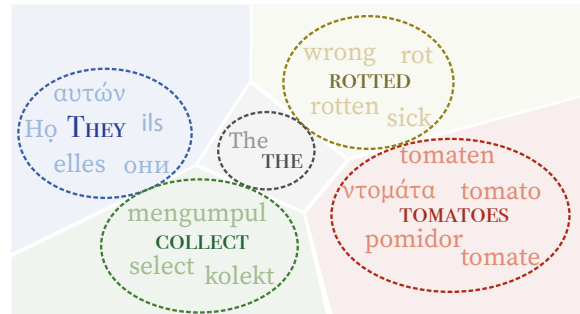

Figure 1: Words with similar meanings or inflectional changes fall under semantic concepts as indicated by the colors. The sentence “They collected the rotted tomatoes.” is found from XNLI.

still conveys the overall sentence meaning. Finally, even the words are replaced into ones that are only vaguely related in semantics, e.g., from “rotted” to “wrong”, resulting in a phrase that is ambiguous and almost incorrect: “wrong tomatoes”, the sentence meaning could still be somewhat speculated and in line with the original sentence.

Given these words contribute similarly to the general sentence understanding in human perception, in this work, we take an initial step towards measuring the role of shared semantics among subwords in the multilingual language models. Specifically, we investigate *to which degree the semantically-similar subwords could share the same word embedding*. Based on the existing multilingual language models (mLM), we form the “semantic tokens” by grouping the subwords based on the similarity of their word embeddings, which henceforth share the same “semantic embedding”.<sup>2</sup> The updated mLMs are evaluated on 5 downstream tasks, which cover 30 languages in total and include both classification and embedding tasks.

<sup>2</sup> We understand that the formed semantic tokens are not perfect and may contain subwords of loosely related or unrelated meanings. On one hand, we provide inspection on the formed semantic tokens in Figure 8 and 13, which suggest that the grouped tokens could reflect coherent semantics. On the other hand, we consider our results as a lowerbound, where techniques that form more accurate semantic tokens are likely to further improve the downstream effectiveness.

\*Work is done during student researcher at GDM.

<sup>1</sup> “они”: “they” in Russian; “tomate”: “tomato” in Spanish

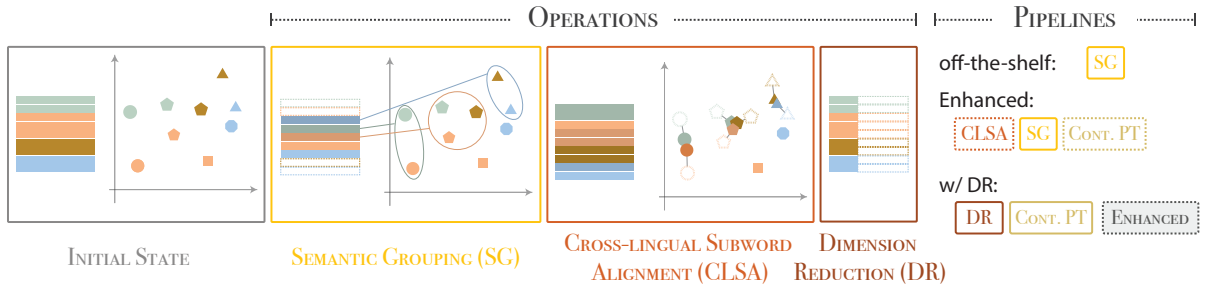

Figure 2: Illustrations of the operations that modify the word embeddings and the pipelines composed of these operations. “Cont. Pt”: Continual Pretraining, whose illustration is skipped due to its prevalence. The colored rows represent the embeddings of the subwords and the coordinate depicts their spacial distances. The shapes indicate the underlying semantics and the colors indicate the languages of the subwords. Under the “PIPELINES”, the solid boxes denote the required operations that are core to the pipeline or essential to the model functionality; the dashed boxes denote the optional operations that are only to provide additional improvement. Better viewed in color.

We find that with a small number of semantic tokens and their embeddings, the mLMs could preserve a majority of the downstream effectiveness: semantic tokens in 5% of the original vocabulary size achieve 90% of the effectiveness on classification tasks, and 20% of the semantic tokens achieve over 85% effectiveness on the embedding tasks. These suggest that while nuances exist in the meaning of each subword, the general semantics representations could get the models a long way in prediction-making.

Next, we eliminate the confounding factor of embedding size: While forming the semantic tokens, the number of the word embedding parameters is also reduced. Does the change in effectiveness reflect the changes on subwords or the reduced embedding parameters? We thus apply the semantic grouping on the word embeddings with reduced parameter size via truncating the embedding dimension, finding that the same observation persists even when the parameters could not be further reduced via dimension reduction, This suggests that the above results are not confounded by the embedding size but a result of the semantic grouping.

Additional experiments suggest that the finding generalizes to the multilingual models with different tokenizers and model sizes. Inspection shows that the grouped subwords indeed exhibit a wide range of semantic similarities: numbers, punctuations, synonyms, and translations across multiple languages under different scripts. Lastly, we found that the zero-shot results on certain classification tasks with semantic tokens are on par or even better than the original models, suggesting that the shared subword-level semantics may serve as the transfer anchors for the cross-lingual generalization.

Our contributions are as follows: **(1)** We found that mLMs could preserve a majority of the downstream effectiveness with a small number of shared subword-level semantics; **(2)** We show that the findings are general across the mLMs with different tokenizers, model sizes, and other aspects; **(3)** Inspection reveals that the grouped subwords exhibit a wide range of semantic similarities; **(4)** The zero-shot results suggest that the shared subword-level semantics may serve as the transfer anchors for cross-lingual generalization.

## 2 Operations and Pipelines

The experiment setting in this paper can be categorized into several pipelines composed of multiple independent operations, centering on semantic grouping. All operations except the continual pretraining only affect the vocabulary  $V$  and word embeddings  $E \in R^{(|V|, D)}$ , where  $|V|$  is the vocabulary size and  $D$  is the initial word embeddings dimension. Figure 2 illustrates all operations except the continual pretraining due to its prevalence, as well as the pipelines composed of the operations.

### 2.1 Semantic Grouping (SG)

Given the vocabulary  $V$  and its word embeddings  $E$ , multiple semantically similar subwords are grouped as a single “semantic” token and henceforth share the same word embedding. The embedding of the semantic token is then initialized by the averaged embeddings of grouped words. That is, after the grouping, the updated LM has a new vocabulary  $V'$  composed of semantic tokens and new word embeddings  $E'_{vocab} \in R^{(|V'|, D)}$ , where  $|V'| < |V|$ . We define the grouping ratio as  $r_G = |V'|/|V|$ .

Dataset Name	Task Name	Task Type	Granularity	# L.	Languages
MasakhaNER	NER	classification	word-level	10	am, ha, ig, rw, lg, sw, wo, yo, luo, pcm
XNLI	NLI	classification	sentence-level	15	ar, bg, de, el, en, es, fr, hi, ru, sw, th, tr, ur, vi, zh
TyDi QA	QA	classification	sentence-level	11	ar bn, en, fi, d, ja, ko, ru, sw, te, th
MIRACL	P Retrieval P Reranking	classification embedding	sentence-level	18	ar, bn, de, en, es, fa, fi, fr, hi, id, ja, ko, ru, sw, te, th, yo, zh

Table 1: Downstream Tasks and Datasets. “P Retrieval”: Passage Retrieval; “P Reranking”: Passage Reranking.

**K-Means.** Subwords are grouped via K-Means based on the cosine distance of their word embeddings. We chose K-Means due to its flexibility on the produced number of groups  $|V'|$ , and use the cosine distance as experiments show that it has better performance especially at high word embeddings dimension (Ap. E). The inspections on the groups show that they could reflect coherent semantics (Figure 8 and 13). In this work, we set  $|V'|$  that corresponds to grouping ratio  $r_G \in \{5\%, 10\%, 20\%, 40\%\}$ .<sup>3</sup>

**First- $k$ .** As the baseline, we keep only the first- $k$  emerged subwords while training the tokenizer, where  $k = |V'|$ . In this way, the size of the vocabulary and word embeddings vector remains the same as the corresponding semantically grouped models, yet each embedding only corresponds to a single subword as the original LM.

## 2.2 Cross-lingual Subword Alignment (CLSA)

Other than running K-Means on the off-the-shelf word embedding, we investigate manually aligning the embedding of subwords across different languages. Specifically, we gather cross-lingual word pairs from the bilingual dictionaries (i.e., MUSE; Conneau et al., 2017; PanLex<sup>4</sup>) and the concept lists of multilingual words (i.e., Concepticon; List et al., 2016; ColexNet; Liu et al., 2023). We filter the words so that only the ones that are tokenized into a single subword are preserved. Then, the word embeddings are trained on InfoNCE loss (Oord et al., 2018) with in-batch negatives. Note that only the parameters of word embeddings are used and updated in this operation, while the rest of the models remain untouched. The training configurations of the CLSA operation are provided in Ap. 11, as well as the ablations on the source datasets used for CLSA training.

<sup>3</sup> We also investigate grouping based on bilingual lexical mappings in pilot studies. See results comparison in Ap. F.

<sup>4</sup> <https://panlex.org/>

## 2.3 Dimension Reduction (DR)

Section 4.2 involves experiments that reduce the dimension of word embedding, where we simply *remove* the final  $D - d$  dimensions of the word embeddings to form the new word embeddings  $E'_d \in R^{(|V|,d)}$  ( $d < D$ ), and pad each embedding vector with zero on the fly. Note that the positional and token-type embeddings are not affected by this operation. While there are alternative options to reduce the word embeddings parameters, we adopt DR for its simplicity and to minimize the change in model architecture. Due to its great modifications to the word embedding, this operation is always followed by continual pretraining (Section 2.4).

## 2.4 Continual Pretraining

The above operations may lead to a potential mismatch between the word embeddings and the rest of the model parameters. To fix the mismatch, we continually pretrain the entire LM using Masked Language Modeling (MLM) objectives to align the updated embedding and language model parameters (Devlin et al., 2019). All continual pretraining uses Wikipedia data of 28 languages,<sup>5</sup> where the languages are selected based on the coverage of downstream tasks. Details on the configurations are provided in Ap. A.

## 3 Downstream Tasks Evaluation

All configurations are evaluated on five multilingual downstream tasks, where four are classification and one is embedding. The classification tasks include word-level understanding, sentence-level understanding, and passage reranking, whereas the embedding task include passage retrieval. All evaluation datasets cover at least 10 diverse languages. See Table 1 for datasets details. We hope these provide a comprehensive evaluation regarding the task nature, the model structures, and the languages.

<sup>5</sup> ar, bg, bn, de, el, en, es, fa, fi, fr, ha, hi, id, ig, ja, ko, lg, ru, rw, sw, te, th, tr, ur, vi, wo, yo, zh

Figure 3: Results of mBERT with vocabulary and embeddings after semantic grouping (SG) or simply reduced size (First- $k$ ). **x-axis**: the grouping ratio  $r_G$  in log scale. The background colors indicate the relative performance to the oracle results, i.e., continual pretrained mBERT with full vocabulary, indicated by the green dashed lines on top. **green**: >90%, **yellow**: 70%–90%, **red**: 50%–70%. The scores of First- $k$  at  $r_G = \{5\%, 10\%\}$  are skipped in the figures as they greatly skew the y-axis.

Figure 4: Results of mBERT after semantic grouping (SG) **with** and **without** applying cross-lingual subword alignment (CLSA). Background colors design are identical to Figure 3.

**MasakhaNER** (Adelani et al., 2021) is a named entity recognition (NER) benchmark including 10 under-represented African languages. We use the version 1.0 in this work.

**TyDiQA-GoldP** (Clark et al., 2020) is the gold passage task of TyDiQA (Clark et al., 2020), a question answering (QA) dataset that includes 11 topologically different languages. It requires to predict the correct answer from the gold answer passage. We refer to it as TyDiQA for simplicity.

**XNLI** (Conneau et al., 2018) is a natural language inference (NLI) dataset that extend the development and test sets of MultiNLI (Williams et al., 2018) to 15 diverse languages.

**MIRACL** (Zhang et al., 2023) is a monolingual information retrieval dataset that provides training data for 16 diverse languages and evaluation data for additional 2 languages. Two tasks are performed on MIRACL: passage retrieval and passage reranking, which fall under embedding and classification tasks respectively. In the rest of the paper, MIRACL refers to the passage retrieval task and MIRACL (rerank) refers to the passage reranking task. We use the classic DPR (Karpukhin et al., 2020) and monoBERT (Nogueira and Cho, 2019; Nogueira et al., 2019) models for each task.

## 4 Results and Analysis

### 4.1 Semantic Grouping (SG)

Figure 3 shows the results of applying SG on mBERT (Devlin et al., 2019) to different degree of grouping ratio  $r_G$  (x-axis). The backgrounds are divided into different colors to highlight the range of the relative performance to the oracle results, i.e., the original mBERT with continual pretraining applied. Each point in the figures shows the *average* score over all the languages under the corresponding configuration.<sup>6</sup>

**The semantically-similar subwords could share the same embeddings to a large degree.** On the classification tasks (the left four sub-figures), applying the SG alone (the **blue** dashed lines) could already preserve over 90% performance on the downstream tasks with 10% original vocabulary size. After applying continual pretraining (the **blue** solid lines), the same level of performance (> 90%)

<sup>6</sup> Due to space limit, Section 4 only provides visualization of all the results, where the numerical scores could be found in Ap. G, Table 5.

<sup>6</sup> We investigate the impact on each single language. While the overall trend per language is similar, we do not observe a consistent impact over languages across different benchmarks. See discussion in Ap. C.

could be preserved with only 5% original vocabulary size. The embedding task (the rightmost sub-figure) is comparatively more sensitive to the semantic grouping, yet still maintains over 85% effectiveness with 20% original vocabulary size after the continual pretraining. The different behaviors suggest that the classification tasks may require only coarse semantic representations to make the prediction, while the embedding tasks require more fine-grained lexical representations to produce reasonable sentence- or passage-level representations.

**Comparison with First- $k$ .** Figure 3 also shows the results of First- $k$  (the red lines) described in Section 2.1. This is to compare SG with mLMs that have the same number of word embedding entries by adopting a smaller vocabulary size. As the figure shows, while First- $k$  could still share similar performance as SG at  $r_G = 40\%$ , removing more subwords from the vocabulary deteriorates the performance drastically on all downstream tasks, regardless of whether continual pretraining is applied. This pair of results suggests that while simply reducing the number of subwords has a detrimental effect on the mLMs capacity, which echoes previous findings on the vocabulary size (Conneau et al., 2020; Liang et al., 2023; Ali et al., 2024; Tao et al., 2024), not all subwords requires an unique representation. In other words, the effect of the number of the word embedding entries should be disentangled from the size of the vocabulary.

**Enhance the semantic similarity via post-hoc operations.** In above results, the semantic grouping is applied on the off-the-shelf mLMs, exploiting the spatial structure of the untouched word embedding. *Could the semantic similarities be further enhanced by post-hoc operations on the mLMs?* We show that this direction is possible and promising, using the cross-lingual subword alignment (CLSA) operation as an example.

Figure 4 compares the results of applying SG on mBERT with and without CLSA, where the orange lines are consistently higher than or similar to the blue ones regardless of whether the model has been continually pretrained. On certain datasets, e.g., XNLI and MIRACL, CLSA brings visible improvement at all grouping ratios, whereas the improvement is more significant at lower grouping ratios on the other datasets. This shows that the semantic similarity among the subwords has room to be improved by post-hoc operations.<sup>7</sup>

<sup>7</sup> It is worth noting that, CLSA is not being proposed as a

## 4.2 Eliminating the Confounding Effect of Embedding Parameters

While applying the SG, the number of the word embedding parameters is also reduced by the same degree. Does the changes on effectiveness truly reflect the semantic grouping, or that any form of word embedding parameters reduction have the same effect? To address the concern, we apply SG on word embeddings with reduced embedding dimension via the dimension reduction (DR) operation, to see whether the effectiveness diminishes as the embedding parameters are reduced. We first show that SG maintains the same level of effectiveness on the reduced dimensions. Moreover, while the embedding dimension has reached its limit, SG could further push down the overall word embedding parameters to a level that could not be achieved by reducing the word embedding dimension alone.

**SG maintain same level of effectiveness with reduced embedding dimensions.** Figure 5 shows the results of SG with three word embedding dimensions  $d \in \{768, 128, 32\}$ , with both CLSA and continual pretraining applied. While DR reduces the effectiveness of the mLM with full vocabulary, the slope of the curve flattens as the dimension reduces, indicating less relative performance drop on the downstream tasks at lower embedding dimension  $d$ . Specifically, the SG results on embedding dimension  $d = 32$  is on par and even outperform the results on the initial dimension  $d = 768$  as vocabulary size reaches 5%. These results show that the effect of SG is largely independent from the embedding parameters.

**SG achieves lower number of embedding parameters beyond dimension reduction.** Apart from the above observation, Figure 6 unites the results of SG at embedding dimension  $d = 32$  and DR from the perspective of the total number of word embedding parameters (x-axis). The brown lines show the DR results of reducing the embedding dimension  $d$  from 768 to  $\{2, 8, 32, 128\}$  with

general solution but only as a proof-of-concept: As mentioned in Section 2.2, CLSA is applied on subwords that are complete words by themselves but not the partial words, which limits the coverage on the entire vocabulary intrinsically. For example, only 45.4% of the subwords in the mBERT vocabulary are covered in the CLSA training set. Instead of promoting the CLSA method itself, we use its success in enhancing the semantic similarity as a proof of concept to show that further post-hoc operations on the word embedding could be beneficial. More effective methods could be studied and applied in a drop-in manner to achieve better semantic grouping results.

Figure 5: Results of semantic grouping with word embedding dimension  $d \in \{768, 128, 32\}$ , with CLSA and continual pretraining. Background colors design are identical to Figure 3. The relative performance of all classification tasks are higher than 90%, thus with full green background.

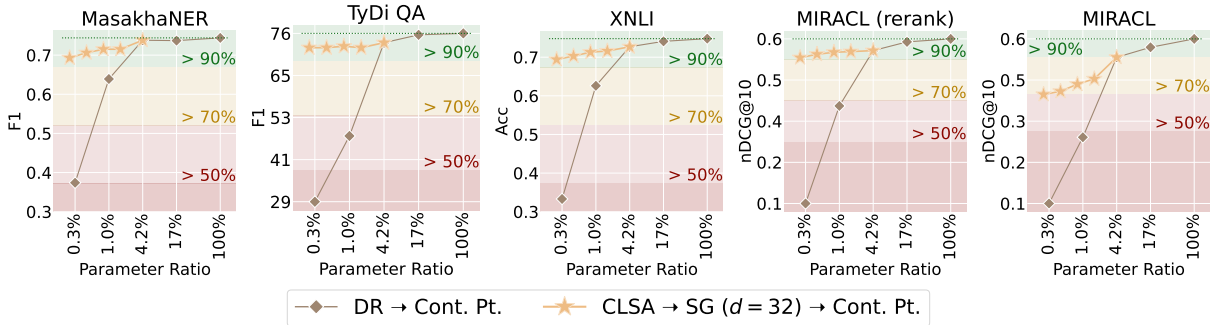

Figure 6: Comparison the effectiveness of Dimension Reduction (DR) and semantic Grouping (SG) at the same level of word embedding parameters size. **x-axis**: the ratio of the word embedding size after DR or SG in log scale. The **brown** lines: DR with dimension  $d \in \{2, 8, 32, 128, 768\}$  and full vocabulary, corresponding to embedding parameters ratio of  $\{0.3\%, 1.0\%, 4.2\%, 17\%, 100\%\}$ . The **yellow** lines: SG with dimension  $d = 32$  and vocabulary grouping ratio  $r_G \in \{5\%, 10\%, 20\%, 40\%\}$ , corresponding to embedding parameters ratio of  $\{0.21\%, 0.42\%, 0.84\%, 1.7\%, 4.2\%\}$ . Background colors design are identical to Figure 3.

the vocabulary untouched, yielding to embedding parameters ratio of  $\{0.3\%, 1.0\%, 4.2\%, 17\%\}$ . With DR, the performance on all downstream tasks is largely preserved until dimension  $d = 32$  and drop sharply once the dimension falls beneath it, indicating that saving the embedding parameters via dimension reduction has reach its limit.

On the other hand, the **yellow** lines shows the models starting from word embedding with dimension  $d = 32$  (thus 4.2% embedding parameters) and then applied SG with grouping ratio  $r_G$  from 40% to 5%,<sup>8</sup> yielding to embedding parameters ratio from 4.2% to 0.21%. The effectiveness differences between the two lines are clear: while further reducing the embedding parameters by similar scale, SG could largely preserve the downstream performance whereas DR fails miserably. This strongly informs that SG is complementary to DR on their effect towards the word embedding parameters, and that it may provide a new perspective on understanding the necessary parameters in the word embeddings.

<sup>8</sup> Identical to the yellow lines in Figure 5.

### 4.3 Backbones

Experiments above are all based on mBERT (Devlin et al., 2019), how would the findings generalize to mLMs with different tokenization algorithm, vocabulary size, model size, and pre-training corpora? We select three additional mLMs to address the above concern: XLM-R (base), XLM-R (large) (Conneau et al., 2020), and XLM-V (base) (Liang et al., 2023), which all deploys ULM (Kudo and Richardson, 2018) to construct the vocabulary, and pretrained on CC100, but differ from each other in model size or tokenization pre-processing, vocabulary allocation and size.

Results of SG are shown in Figure 7, where the background colors are removed as different backbones do not share the same oracle results. Instead, we compare the results with mBERT (the **blue** lines) to see whether they follow similar trend as more subwords are semantically grouped. Overall, the slopes of the four curves are similar on all five benchmarks, indicating that the findings are likely to generalize over different multilingual LMs with different tokenizers, and model sizes.

Figure 7: Results of SG on multiple backbones, all with CLSA applied and no continual pretraining. All models shows similar trend regarding semantically grouped subwords.

#### 4.4 Semantic Similarities Categories among the Grouped Subwords

This section aims to provide some intuitions on how “semantically similar” the grouped subwords are. Figure 8 provides examples of the semantic groups based on model with embedding dimension  $d = 768$  and CLSA applied.<sup>9</sup>

Among the eight displayed example groups, six of them are chosen from the Swadesh list, covering pronouns, nouns, adjectives, prepositions, and verbs; the other two are “NUMBERS” and “PUNCTUATIONS”, where we observed strong clustering during manual inspection. We observe multiple patterns of semantic similarities among the grouped subwords:

1. semantically identical or similar words across languages: *mother* vs. *mẹ*, *they* vs. *그들은*.<sup>10</sup>
2. semantically related words from the same language: *at* vs. *on*, *heavy* vs. *hard*.
3. semantically related words across languages: *heavy* vs. *intenso*, *who* vs. *που*.<sup>11</sup>
4. numbers in similar range: *the cluster numbers ranging from 60 to 100*.
5. punctuations: *., ;!*

We also notices some undesired behavior among the grouped subwords: The current methods are limited in the polysemous situation and controlling the desired semantic per group: For example, in the group of “I”, while the desired semantic is the first person singular pronouns in different languages, the group mainly includes the single letter such as “A”, “B”, “C” on mLMs with  $d = 768$ , as shown by Figure 13 in Ap. H, suggesting that future work is necessary to better handle such cases.

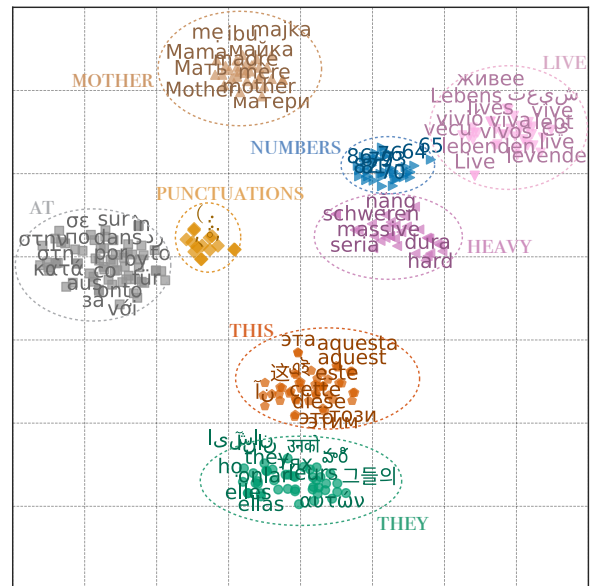

Figure 8: Eight “semantic tokens” formed by grouped subwords on mBERT word embedding with dimension  $d = 768$  and CLSA applied. The labels outside the circles are either the keyword of the cluster, or “NUMBERS”/“PUNCTUATIONS” if the cluster is a collection of numbers/punctuations.

#### 4.5 Cross-lingual Transfer

Lastly, we investigate that how the semantic grouping affects the cross-lingual transferability from English to other languages. We evaluate on four of the above tasks, where MasakhaNER is skipped as English training data is not available.

Surprisingly, on two classification tasks: TyDiQA and MIRACL (rerank), the zero-shot results at grouping ratio  $r_G = 40\%$  are on par or even better than the oracle results, where SG is not applied. These might suggest that the fine-grained subword-level semantics serve as the anchors for cross-lingual transferring in some circumstances.

On the other hand, the cross-lingual transferring on embedding tasks is more challenging especially with the course-grained semantics. While the zero-shot results on MIRACL at  $r_G \in \{20\%, 40\%\}$  are

<sup>9</sup> Only parts of the subwords are displayed per group for space limit. For the full list of subwords, please refer to Ap. H and Figure 13.

<sup>10</sup> *mẹ*: “mother” in Vietnamese; *그들은*: “they” in Korean.

<sup>11</sup> *intenso*: “intense” in Spanish; *που*: “where” in Greek.

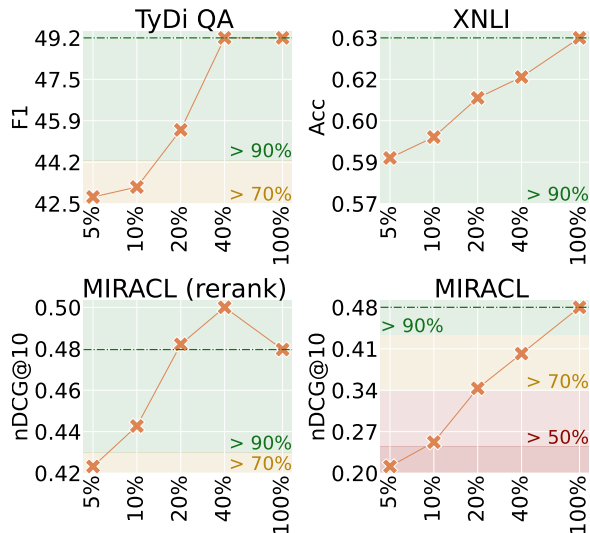

Figure 9: Results when transferring from English to other languages on four benchmarks, with CLSA and continual pretraining applied. MasakhaNER is skipped as English training data is not available. Background colors design are identical to Figure 3. The dashed green line denotes the zero-shot performance without semantic grouping.

still in the reasonable range (i.e., more than 70% of the relative zero-shot effectiveness), the relative zero-shot falls under 50% when  $r_G$  further drops. This echoes with the in-domain results above that embedding tasks requires a more fine-grained semantic information from the subwords.

## 5 Related Works

**Semantic Similarities in Word Embedding.** The semantics latent knowledge in word embeddings have been leveraged to adapt the pretrained multilingual LMs to unseen languages or scripts (Pfeiffer et al., 2021; Wang et al., 2022; Liu et al., 2023). While it has been shown that the shared semantics assist the language transfer, it was unclear how much the semantics alone could achieve compared to the full-fledged models.

**Parameter Redundancy and Model Compression.** Dalvi et al. (2020) study the layer and neuron redundancy on BERT and XLNet, and many works proposed to compress the overall model size via pruning (Gordon et al., 2020; Ashkboos et al., 2024; Yang et al., 2024), knowledge distillation (Turc et al., 2019; Sanh et al., 2019), and quantization (Shen et al., 2020). From the perspective of model compression, our work provides a new view on the word embeddings redundancy from shared semantics among subwords.

**Bilingual Lexicon Induction and Word Alignment.** The Cross-lingual Subword Alignment (CLSA) operation is related to the task of *Bilingual Lexicon Induction (BLI)* and *Word Alignment*. BLI aims to induce the equivalent translation in language  $L_2$  given a word in language  $L_1$  (Artetxe et al., 2016; Conneau et al., 2017; Wang et al., 2020; Shi et al., 2021). CLSA is similar to BLI in terms of focusing on uncontextualized cross-lingual words pairs, but different in that it aims to align the word pairs in the embedding space and targets on not only bilingual but also multilingual words. Word alignment aims to find bilingual word pairs in parallel sentences (Cao et al., 2020; Jalili Sabet et al., 2020). While the name is similar, the goals are different: In addition to above differences with BLI, CLSA focuses on uncontextualized cross-lingual word pairs and does not involve parallel sentences.

**Word Sense Clustering.** The Semantic Grouping (SG) operation is also related to the task of word sense clustering. While with similar objectives, the word sense clustering was mainly constructed based on the corpora statistics (Snow et al., 2007), while the SG operation is based on the word embeddings similarity.

## 6 Conclusion

Inspired by the robustness of human perception to the semantically similar words, this work measures the role of shared semantics in the subwords of the multilingual word embeddings, finding that the general shared semantics could get the models a long way in understanding languages and making predictions. Additional experiments shows that the observations generalize across mLMs with different tokenization algorithm, vocabulary size, model size, and pre-training corpora. Inspections on the grouped subwords show that they exhibit multiple patterns of semantic similarity, including synonyms and word translations in many languages.

Not only the subword-level semantics is prominent in in-domain language understanding, in some cases, it also serves as the anchors of cross-lingual transferring and thus potentially a promising direction of bridging the understanding of different languages. We hope that this work sheds lights on understanding the multilingual vocabulary and word embeddings from the semantic perspective, and spur further research on the subword-level information sharing across languages.

## Limitations

**The scope of Semantics.** This work only discuss the application scenario where pragmatics are not heavily involved. The other situations such as poetry, humour, sentiment analysis intuitively would require not only the semantic meanings, but also exquisite understanding of the words nuances, yet out of the scope of this work. Similarly, the work is probably not applicable to figurative language such as metaphor, irony, etc.

**Word-level Semantics Only.** One of the major limitation of this work is not consider the phrase-level semantics in the study.

**Encoder-only tasks.** As a natural limitation of the semantical grouping method itself, it is not straightforward to apply the method to decoder-only models since it forbit predicting explicit subword at each decoding step. Thus only the encoder-only tasks are evaluated in this work. Further design and exploration would be required to apply the method to decoder-only models.

**Results on Embedding Tasks.** Results show that the embedding tasks are more sensitive to the semantical grouping compared to the classification tasks. More questions could be raised from the phenomenon: does it make embedding task a better evaluation metrics for the semantical grouping, or that simply the embedding task require more fine-grained understanding of the subword information? How much could be embedding benefit if the semantical grouping algorithm could be improved? We believe that these are important questions to further understand effectiveness and *limitation* of this direction. Limited by the paper capacity, we leave them for future exploration.

Table 2: Downstream task training configurations. **mNER: MasakhaNER**

## A Training and Evaluation Configurations

**Continual Pretraining.** All continual pretraining in this work share the same hyperparameters. Language models are trained on the MLM objective for 25,000 steps, with a batch size 1024 and a learning rate of  $1e - 4$ . We randomly masked 15% of the tokens. The hyperparameters were chosen following the initial pretraining configurations of [Devlin et al. \(2019\)](#).

**Downstream Task.** For each task, we use all the available training data provided by each dataset. The training configurations are provided in [Table 2](#).

## B Alignment Datasets

[Figure 11](#) compares the impact of different word alignment datasets on the downstream tasks. All experiments are followed by  $r_G = 5\%$  semantic grouping and continual pretraining. On all downstream datasets, we compare the results of using four groups of alignment data:

1. MUSE
2. MUSE and Round-Trip
3. MUSE and PanLex
4. MUSE, PanLex, Colex, and Concepticon

where Round-Trip are the pair of word that are the nearest neighbors to each other in the embedding space, serving as a regularization in the CLSA procedure. We found that scenario 4 gives the best overall results, and thus use it as our default configuration.

## C Impact on Individual Languages

This section explores whether the languages are consistently affected across tasks by the semantic grouping. To this end, we compare the effectiveness drop on the overlapping languages of each pair of benchmarks, and compute their Pearson correlation coefficient. Five pairs of benchmarks are selected for analysis, which fall under 3 groups:

Figure 10: Pearson correlation between the relative performance drop per language between a pair of benchmarks. Each row indicates a pair of benchmarks, where (bi) refers to retrieval (which uses bi-encoder) and (cross) refers to reranking (which uses cross-encoder). Each column indicates a semantic grouping rate  $r_G$ . *Left*: Pearson correlation coefficient  $\rho$ ; *Right*: corresponding one-tail p-values.

### I. different task types and data sources:

- (a) MIRACL (retrieval) vs. XNLI
- (b) MIRACL (rerank) vs. TyDiQA

### II. different tasks types, same data source:

- MIRACL (retrieval) vs. MIRACL (rerank)

### III. same task type, different data sources:

- (a) MIRACL (rerank) vs. XNLI
- (b) MIRACL (rerank) vs. TyDiQA

The benchmark selection is mainly under the consideration of the number of overlapping languages: MasakhaNER have no overlapping languages with the other datasets, and TyDiQA and XNLI only have 3 overlapping languages.

[Figure 10](#) shows Pearson correlation coefficient  $\rho$  (left) and the corresponding p-values (right) in two heatmaps. In two heatmaps, higher saturation indicates higher  $\rho$  or smaller p-values, respectively, which together indicates stronger correlations in higher confidence. Each row corresponds to a pair of benchmarks, and each column corresponds to a semantic grouping ratio  $r_G$ . The three blocks in the figure corresponds to the three groups defined above from top to bottom.

Overall, we observe consistent trend on the two heatmaps, where the top-2 rows are smaller in the coefficient  $\rho$  (lighter color in the left heatmap) and larger in p-values (darker color in the right heatmap), and that the bottom-3 rows are larger in the coefficient  $\rho$  and smaller in p-values. This indicates that languages are affected similarly by the semantic grouping when the benchmarks pair share either the same data source (group 2) or the task type (group 3). In contrast, the impact on the languages is less consistent across benchmarks that shares neither the task type nor the data source (group 1).

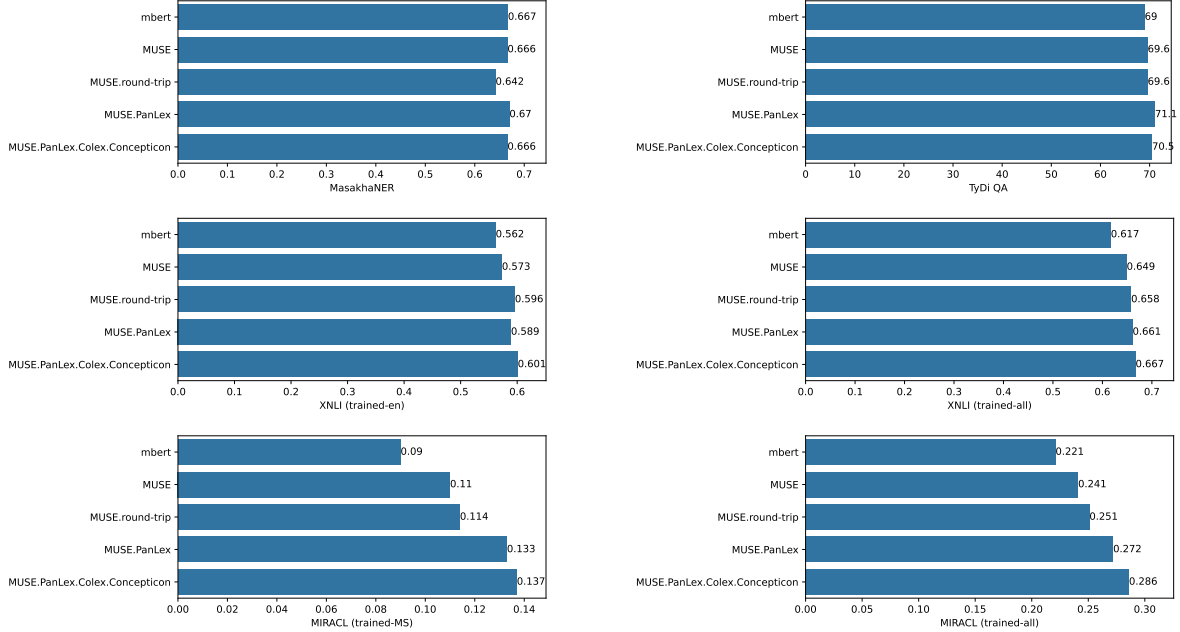

Figure 11: Comparison of alignment source dataset on downstream tasks. Each bar represents one alignment dataset(s), where “mbert” is the baseline result when there is no alignment applied. The x-axis is the average score on all languages per task.

$d$	$r_G$	# Para (M)	GPU Mem (G)	steps / sec
768	5.0%	90	19.1	5.1
	10.0%	95	39.8	2.6
	20.0%	104	51.5	2.1
	40.0%	123	74.9	2.1
	100.0%	178	74.6	1.9
128	5.0%	86	19.1	5.2
	100.0%	101	74.6	1.9
32	5.0%	86	19.1	5.3
	100.0%	89	74.6	1.9

Table 3: Efficiency statistics of mBERT under SG and DR, collected on a 80G A100 GPU during pretraining with batch size 128 per device. (green: best; red: worse; yellow: neutral)

## D Dissussion on Memory and Efficiency

This section discusses the effect of semantic grouping on the model size, and its memory usage and training speed during the continual pretraining. Table 3 shows above statistics of mBERT with  $r_G \in \{5\%, 10\%, 20\%, 40\%, 100\%\}$  with word embedding dimension  $d = 768$ , and  $r_G \in \{5\%, 100\%\}$  with  $d \in \{128, 32\}$ .<sup>12</sup>

**Model Size.** The model size are affected linearly with the vocabulary size or the word embedding dimension. As the word embedding initially takes

<sup>12</sup>Statistics of LMs with  $r_G \in \{10\%, 20\%, 40\%\}$  and  $d \in \{128, 32\}$  are similar to  $d = 768$ , thus skipped for simplicity.

over half of the total model parameters in mBERT, grouping the subwords to 5% of the vocabulary size brings visible savings on the overall model size, from 178M to 90M.

**Memory.** We found that memory usage during the pretraining could be largely saved via reduced vocabulary size, but not the word embedding dimension. We explain it by that the memory usage during the pretraining is bottlenecked by the activations, especially the final token-level logit matrix, whose size is solely determined by the vocabulary size but not the word embedding dimension. As a result, the memory savings from compact vocabulary is prominent, from 74.6G to 19.1G when reducing the vocabulary size from 100% to 5%, while saving the word embedding dimension barely changes the memory usage.

**Training Speed.** The trend of training speed is similar to the memory usage, where saving the word embedding dimension has negligible effect on the training speed while saving the vocabulary size has significant impact, from 1.9 to 5.1 steps per second.

## E Ablation on Distance Metric

We compare the results using cosine versus Euclidean distance in Figure 12, where the results shows that grouping on Euclidean distance greatly

Method	$r_G$	nDCG@10
Oracle	100%	0.452
Grouping on MUSE (zh)	99.2%	0.357
Grouping on MUSE (5L)	92.1%	0.248
Grouping on MUSE (all)	86.2%	0.193
K-Means	40%	0.304

Table 4: Results on MIRACL (zh), comparing Grouping via Bilingual Lexicons vs K-Means. Models are fine-tuned on MS MARCO, without CLSA or continual pretraining.

underperformance cosine distance especially at higher dimension ( $d = 768$ ). We interpret this as that the vector norm is an undesired feature when pursuing the semantic similarity between the subwords, which amplifies the distance between semantic similar subword at high dimension.

## F Grouping via Bilingual Lexicons

As an intuitive alternative to grouping via K-Means, we explored to group the subwords via the ground-truth bilingual lexicons in the preliminary experiments, finding that it has limited coverage on the subwords, thus grouping ratios, and also underperforming the K-Means-based grouping. See Table 4 for the results.

## G Numerical Results of Experiments in Figure 2–6

Table 5 presents the numerical results of experiments in Figure 3, 4, 5, 6, and 7.

## H More Inspection Examples

Figure 13 shows more examples of the grouped subwords additional to Figure 8.

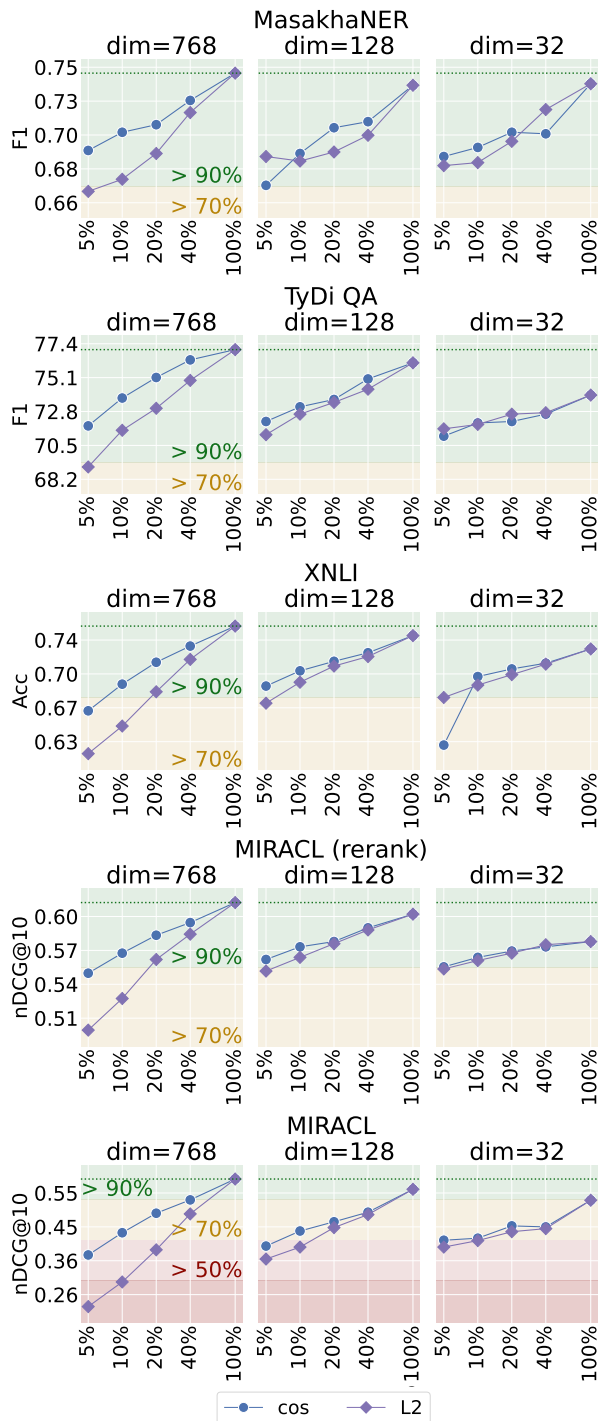

Figure 12: Comparison of L2 versus cosine distance when using K-Means to group the subwords.

Table 5: Numerical results of experiments in all figures, where the each number is the averaged results of all languages per benchmark. We skip the per-language score due to the space limit.  $d$ : word embedding dimension;  $r_G$ : grouping ratio; “cross-”: cross-encoder “bi-”: bi-encoder **perc**: the relative performance to the oracle results (i.e., the second row for mBERT, the corresponding 100% rows for the other backbones) The background colors indicate the relative performance to the oracle results: **green**: >90%, **yellow**: 70%–90%, **red**: 50%–70% and the dark red color means <50%. Better viewed in colors.
